Don't we grab a memcg reference when we fire the cache creation?  
(I did that for slub, can't really recall from the top of my head if  
you are doing it as well)

That would prevent the memcg to go away, while relieving us from the  
need to take a temporary reference for every page while sleeping.

Agree. It was more a question to see if anyone would speak up for it.  
But certainly not me.

Keep in mind that our notion of "fail often" may start to change when we start limiting the amount of kernel memory =p.

Specially in nested cgroups limited by its parent.

So apart from the comment issue, the problem here to me seems to be that:

yes, kmem\_cache\_create failing is rare. But the circumstances in which it can happen all involve memory pressure. And in this case, we'll leave memcg->slabs[idx] as NULL, which means we'll keep trying to create the cache in further allocations.

This seems at best a tricky way to escape the memcg constraint...

I am not sure this is the behavior we want. Have to think a little bit.

```

Sorry If I misled you. But what I remember mentioning, was that it was maybe better to create some of the caches right away, instead of putting the into the workqueue at all. So earlier, rather than later.

That said, how I view this particular issue changed quite a bit over the past days, due to our discussions. Specially, see the last mail I wrote to Kame as reply to your patchset. I think that queuing up stuff in the workqueue may get quite handy in the end.

But in the interest of having less objects scaping memcg, how about we call `cond_resched()` when we can sleep, after we kicked out the worker?

This way we don't need to deal with conditionals for can sleep vs can't sleep, (simpler code), while having the cache created right away when it can.

```

That's not how I read it. Since there is no completion guarantees coming from the workqueue, I really don't see how we can be sure that the data in `cachep->memcg_param.memcg` won't change.

You are right that touching the slab actually happens in `mem_cgroup_get_kmem_cache()`. That is called in `kmem_cache_alloc()`. And the first object is likely to be billed to the parent cgroup (or root)

Now imagine that cache being full, so we need a new page for it. This will quickly lead us to `cache_grow()`, and all the other steps are therefore the same.

So how can we guarantee that the memcg pointer is stable between alloc and free?

No, we're appending the css id now too, precisely to cope with the  
duplicates problem.

/me goes check all the code again...

Does that mean that when two memcg's are creating the same cache they  
will end up with different ids??
