My dedicated server company took 2 weeks to get OpenVZ installed. But thereafter using the 64-bit of everything the server would fail. The indication was the virtual servers (containers) would become inaccessible. Only a hard reboot of the server would restore functionality.

Was this an issue with EXT4 or other issues? I have left Atjeu/Deer Valley Data after the new company took over and made matters worse. I need to know how to tell my new server company to install CentOS 7.x with OpenVZ on top of it. Is there a Wiki page on this specific issue or something helpful?

This is what I have:

This is a short guide to get OpenVZ configured on CentOS 7.

During the install of CentOS 7, be sure to make all file systems apart from swap ext4. OpenVZ is not compatible with the xfs file system. Once you've installed CentOS 7 do not update or do anything except immediately install these packages:

```
yum localinstall http://download.openvz.org/virtuozzo/releases/7.0/x86_64/os/
Packages/v/virtuozzo-release-7.0.0-10.vz7.x86_64.rpm
```

then install:

```
yum install -y prctl prl-disp-service vzkernel
```

Now reboot and afterwards run `uname -r` to make sure you're booted to the vz kernel.

Run:

```
systemctl status vz          // to make sure the vz service is running.
```

You must download templates via yum in order to make containers. To see what templates you already have run

```
rpm -qa | grep '-ez'          // you need to reinstall any that are already there with yum reinstall,
otherwise they may not work.
```

To see which ones you can download run

```
yum search centos             // and look for anything with "ez" on the end.
```

The last thing before you make a container is making the cache with whatever templates you have. Simply run:

```
vzpkg create cache centos-7-x86_64
```

Now you can create a container with that template cache. When you try to create a container leave out everything after the 64, so:

```
vzctl create 101 --ostemplate centos-7-x86_64
```

Have I missed anything???
