Subject: [RFC] Transactional CGroup task attachment
Posted by Paul Menage on Thu, 10 Jul 2008 06:46:33 GMT
View Forum Message <> Reply to Message

This is an initial design for a transactional task attachment framework for cgroups. There are probably some potential simplications that I've missed, particularly in the area of locking. Comments appreciated.

The Problem
==========

Currently cgroups task movements are done in three phases

1) all subsystems in the destination cgroup get the chance to veto the movement (via their can_attach()) callback
2) task->cgroups is updated (while holding task->alloc_lock)
3) all subsystems get an attach() callback to let them perform any housekeeping updates

The problems with this include:

- There's no way to ensure that the result of can_attach() remains valid up until the attach() callback, unless any invalidating operations call cgroup_lock() to synchronize with the change. This is fine for something like cpusets, where invalidating operations are rare slow events like the user removing all cpus from a cpuset, or cpu hotplug triggering removal of a cpuset's last cpu. It's not so good for the virtual address space controller where the can_attach() check might be that the res_counter has enough space, and an invalidating operation might be another task in the cgroup allocating another page of virtual address space.

- It doesn't handle the case of the proposed "cgroup.procs" file which can move multiple threads into a cgroup in one operation; the can_attach() and attach() calls should be able to atomically allow all or none of the threads to move.

- it can create races around the time of the movement regarding to which cgroup a resource charge/uncharge should be assigned (e.g. between steps 2 and 3 new resource usage will be charged to the destination cgroup, but step 3 might involve migrating a charge equal to the task's resource usage from the old cgroup to the new, resulting in over/under-charges.

Conceptual solution
==========

In ideal terms, a solution for this problem would meet the following requirements:

- support movement of an arbitrary set of threads between an arbitrary set of cgroups
- allow arbitrarily complex locking from the subsystems involved so that they can synchronize against concurrent charges, etc
- allow rollback at any point in the process

But in practice that would probably be way more complex than we'd want in the kernel. We don't want to encourage excessively-complex locking from subsystems, and we don't need to support arbitrary task movements.

(Hopefully!) Practical solution
==========

So here's a more practical solution, which hopefully catches the important parts of the requirements without being quite so complex.

The restrictions are:

- only supporting movement to one destination cgroup (in the same hierarchy, of course); if an entire process is being moved, then potentially its threads could be coming from different source cgroups
- a subsystem may optionally fail such an attach if it can't handle the synchronization this would entail.

- supporting moving either one thread, one entire thread group or (for the future) "all threads". This supports the existing "tasks" file, the proposed "procs" file and also allows scope for things like adding a subsystem to an existing hierarchy.

- locking/checking performed in two phases - one to support sleeping locks, and one to support spinlocks. This is to support both subsystems that use mutexes to protect their data, and subsystems that use spinlocks

- no locks allowed to be shared between multiple subsystems during the transaction, with the single exception of the mmap_sem of the thread/process being moved. This is because multiple subsystems use the mmap_sem for synchronization, and are quite likely to be mounted in the same hierarchy. The alternative would be to introduce a down_read_unfair() operation that would skip ahead of waiting writers, to safely allow a single thread to recursively lock mm->mmap_sem.

First we define the state for the transaction:

```
struct cgroup_attach_state {

  // The thread or process being moved, NULL if moving (potentially) all threads
  struct task_struct *task;
  enum {
    CGROUP_ATTACH_THREAD,
    CGROUP_ATTACH_PROCESS,
    CGROUP_ATTACH_ALL
  } mode;

  // The destination cgroup
  struct cgroup *dest;

  // The source cgroup for "task" (child threads *may* have different
groups; subsystem must handle this if it needs to)
  struct cgroup *src;

  // Private state for the attach operation per-subsys. Subsystems are
completely responsible for managing this
  void *subsys_state[CGROUP_SUBSYS_STATE];

  // "Recursive lock count" for task->mm->mmap_sem (needed if we don't
introduce down_read_unfair())
  int mmap_sem_lock_count;
};
```

New cgroup subsystem callbacks (all optional):

```
int prepare_attach_sleep(struct cgroup_attach_state *state);
```

Called during the first preparation phase for each subsystem. The subsystem may perform any sleeping behaviour, including waiting for mutexes and doing sleeping memory allocations, but may not disable interrupts or take any spinlocks. Return a -ve error on failure or 0 on success. If it returns failure, then no further callbacks will be made for this attach; if it returns success then exactly one of abort_attach_sleep() or commit_attach() is guaranteed to be called in the future

No two subsystems may take the same lock as part of their prepare_attach_sleep() callback. A special case is made for mmap_sem: if this callback needs to down_read(&state->task->mmap_sem) it should only do so if state->mmap_sem_lock_count++ == 0. (A helper function will be provided for this). The callback should not

write_lock(&state->task->mmap_sem).

Called with group_mutex (which prevents any other task movement
between cgroups) held plus any mutexes/semaphores taken by earlier
subsystems's callbacks.

---

int prepare_attach_nosleep(struct cgroup_attach_state *state);

Called during the second preparation phase (assuming no subsystem
failed in the first phase). The subsystem may not sleep in any way,
but may disable interrupts or take spinlocks. Return a -ve error on
failure or 0 on success. If it returns failure, then
abort_attach_sleep() will be called; if it returns success then either
abort_attach_nosleep() followed by abort_attach_sleep() will be
called, or commit_attach() will be called

Called with cgroup_mutex and alloc_lock for task held (plus any
mutexes/semaphores taken by subsystems in the prepare_attach_nosleep()
phase, and any spinlocks taken by earlier subsystems in this phase .
If state->mode == CGROUP_ATTACH_PROCESS then alloc_lock for all
threads in task's thread_group are held. (Is this a really bad idea?
Maybe we should call this without any task->alloc_lock held?)

---

void abort_attach_sleep(struct cgroup_attach_state *state);

Called following a successful return from prepare_attach_sleep().
Indicates that the attach operation was aborted and the subsystem
should unwind any state changes made and locks taken by
prepare_attach_sleep().

Called with same locks as prepare_attach_sleep()

---

void abort_attach_nosleep(struct cgroup_attach_state *state);

Called following a successful return from prepare_attach_nosleep().
Indicates that the attach operation was aborted and the subsystem
should unwind any state changes made and locks taken by
prepare_attach_nosleep().

Called with the same locks as prepare_attach_nosleep();

---

void commit_attach(struct cgroup_attach_state *state);

Called following a successful return from prepare_attach_sleep() for a subsystem that has no prepare_attach_nosleep(), or following a successful return from prepare_attach_nosleep(). Indicates that the attach operation is going ahead, and
any partially-committed state should be finalized, and any taken locks should be released. No further callbacks will be made for this attach.

This is called immediately after updating task->cgroups (and threads if necessary) to point to the new cgroup set.

Called with the same locks held as prepare_attach_nosleep()

Examples
==========

Here are a few examples of how you might use this. They're not intended to be syntactically correct or compilable - they're just an idea of what the routines might look like.

1) cpusets

cpusets (currently) uses cgroup_mutex for most of its changes that can invalidate a task attach. thus it can assume that any checks performed by prepare_attach_*() will remain valid without needing any additional locking. The existing callback_mutex used to synchronize cpuset changes can't be taken in commit_attach() since spinlocks are held at that point. However, I think that all the current uses of
callback_mutex could actually be replaced with an rwlock, which would be permitted to be taken during commit_attach(). The cpuset subsystem wouldn't need to maintain any special state for the transaction. So:

- prepare_attach_nosleep(): same as existing cpuset_can_attach()

- commit_attach(): update tasks' allowed cpus; schedule memory migration in a workqueue if necessary (since we can't take locks at this point.

2) memrlimit

memrlimit needs to be able to ensure that:

- changes to an mm's virtual address space size can't occur

concurrently with the mm's owner moving between cgroups (including via
a change of mm ownership).

- moving the mm's owner doesn't over-commit the destination cgroup

- once the destination cgroup has been checked, additional charges
can't be made that result in the original move becoming invalid

Currently all normal charges and uncharges are done under the
protection of down_write(&mm->mmap_sem); uncharging following a change
that was charged but failed for other reasons isn't done under
mmap_sem, but isn't a critical path so could probably be changed to do
so (it wouldn't have to be all one big critical section).
Additionally, mm->owner changes are also done under
down_write(&mmap_sem). Thus holding down_read(&mmap_sem) across the
transaction is sufficient. So (roughly):

```
prepare_attach_sleep() {
  // prevent mm->owner and mm->total_vm changes
  down_read(&mm->mmap_sem);
  // Nothing to do if we're not moving the owner
  if (mm->owner != state->task) return 0;
  if ((ret = res_counter_charge(state->dest, mm->total_vm)) {
    // If we failed to allocate in the destination, clean up
    up_read(&mm->mmap_sem);
  }
  return ret;
}

commit_attach() {
  if (mm->owner == state->task) {
    // Release the charge from the source
    res_counter_uncharge(state->src, mm->total_vm);
  }
  // Clean up locks
  up_read(&mm->mmap_sem);
}

abort_attach_sleep() {
  if (mm->owner == state->task) {
    // Remove the temporary charge from the destination
    res_counter_uncharge(state->dest_cgroup, mm->total_vm);
  }
  // Clean up locks
  up_read(&mm->mmap_sem);
}
```

As mentioned above, to handle the case where multiple subsystems need

to down_read(&mm->mmap_sem), these down/up operations may actually end up being done via helper functions to avoid recursive locks.

3) memory

Curently the memory cgroup only uses the mm->owner's cgroup at charge time, and keeps a reference to the cgroup on the page. However, patches have been proposed that would move all non-shared (page count == 1) pages to the destination cgroup when the mm->owner moves to a new cgroup. Since it's not possible to prevent page count changes without locking all mms on the system, even this transaction approach can't really give guarantees. However, something like the following would probably be suitable. It's very similar to the memrlimit approach, except for the fact that we have to handle the fact that the number of pages we finally move might not be exactly the same as the number of pages we thought we'd be moving.

```
prepare_attach_sleep() {
  down_read(&mm->mmap_sem);
  if (mm->owner != state->task) return 0;
  count = count_unshared_pages(mm);
  // save the count charged to the new cgroup
  state->subsys[memcgroup_subsys_id] = (void *)count;
  if ((ret = res_counter_charge(state->dest, count)) {
    up_read(&mm->mmap_sem);
  }
  return ret;
}

commit_attach() {
  if (mm->owner == state->task) {
    final_count = move_unshared_pages(mm, state->dest);
    res_counter_uncharge(state->src, final_count);
    count = state->subsys[memcgroup_subsys_id];
    res_counter_force_charge(state->dest, final_count - count);
  }
  up_read(&mm->mmap_sem);
}

abort_attach_sleep() {
  if (mm->owner == state->task) {
    count = state->subsys[memcgroup_subsys_id];
    res_counter_uncharge(state->dest, count);
  }
  up_read(&mm->mmap_sem);
}
```

4) numtasks:

Numtasks is different from the two memory-related controllers in that it may need to move charges from multiple source cgroups (for different threads); the memory cgroups only have to deal with the mm of a thread-group leader, and all threads in an attach operation are from the same thread_group. So numtasks has to be able to handle uncharging multiple source cgroups in the commit_attach() operation. In order to do this, it requires additional state:

```
struct numtasks_attach_state {
  int count;
  struct cgroup *cg;
  struct numtasks_attach_state *next;
}
```

It will build a list of numtasks_attach_state objects, one for each distinct source cgroup; in the general case either there will only be a single thread moving or else all the threads in the thread group will belong to the same cgroup, in which case this list will only be a single element; the list is very unlikely to get to more than a small number of elements.

The prepare_attach_sleep() function can rely on the fact that although tasks can fork/exit concurrently with the attach, since cgroup_mutex is held, no tasks can change cgroups, and therefore a complete list of source cgroups can be constructed.

```
prepare_attach_sleep() {
  for each thread being moved:
    if the list doesn't yet have an entry for thread->cgroup:
      allocate new entry with cg = thread->cgroup, count = 0;
      add new entry to list
  store list in state->subsys[numtasks_subsys_id];
  return 0;
}
```

Then prepare_attach_nosleep() can move counts under protection of tasklist_lock, to prevent any forks/exits

```
prepare_attach_nosleep() {
  read_lock(&tasklist_lock);
  for each thread being moved {
    find entry for thread->cgroup in list
    entry->count++;
    total_count++;
  }
  if ((ret = res_counter_charge(state->dest, total_count) != 0) {
```

```
    read_unlock(&tasklist_lock);
  }
  return ret;
}

commit_attach() {
  for each entry in list {
    res_counter_uncharge(entry->cg, entry->count);
  }
  read_unlock(&tasklist_lock);
  free list;
}

abort_attach_nosleep() {
  // just needs to clear up prepare_attach_nosleep()
  res_counter_uncharge(state->dest, total_count);
  read_unlock(&tasklist_lock);
}

abort_attach_sleep() {
  // just needs to clean up the list allocated in prepare_attach_sleep()
  free list;
}
```

So, thoughts? Is this just way to complex? Have I missed something
that means this approach can't work?

Paul
